Abstract

Purpose—*Candida* infective endocarditis (IE) is uncommon but often fatal. Most epidemiologic data are derived from small case series or case reports. This study was conducted to explore epidemiology, treatment patterns, and outcomes of patients with Candida IE.

Methods—We compared 33 *Candida* IE cases to 2716 patients with non-fungal IE in the International Collaboration on Endocarditis - Prospective Cohort Study. Patients were enrolled and data collected from June 2000 until August 2005.

Results—Patients with *Candida* IE were more likely to have prosthetic valves (p<0.001), short term indwelling catheters (p<0.0001), and have healthcare-associated infection (p<0.001). Reasons for surgery differed between the two groups: myocardial abscess (46.7% vs. 22.2% p=0.026) and persistent positive blood cultures (33.3% vs. 9.9%, p=0.003) were more common among those with *Candida* IE. Mortality at discharge was higher in patients with *Candida* IE (30.3%) when compared to non-fungal cases (17%, p=0.046). Among *Candida* patients, mortality was similar in patients who received combination surgical and antifungal therapy versus antifungal therapy alone (33.3% vs. 27.8%, p=0.26). New antifungal drugs, particularly echinocandins, were used frequently.

Conclusions—These multi-center data suggest distinct epidemiologic features of *Candida* IE when compared to non-fungal cases. Indications for surgical intervention are different and mortality is increased. Newer antifungal treatment options are increasingly used. Large, multi-center studies are needed to help better define *Candida* IE.

Introduction

Candida infective endocarditis (IE) is a rare and poorly understood complication of fungemia. Although *Candida* IE has been regarded traditionally as an uncommon infection, rates of fungemia have increased by as much as 128% in recent years, leaving a growing number of patients at risk for this complication[1]. Despite aggressive antifungal and surgical therapy, mortality approaches 80% in some series and a better understanding of this infection is needed [2–4].

Because of the rarity of candidal IE at any single institution, the epidemiology, prognosis, and optimal therapy of *Candida* IE are poorly defined, and treatment guidelines are derived mostly from single-site case series and case reports [3–6]. The recommended treatment of *Candida* IE is an amphotericin B-based regimen plus surgical intervention, often followed by long-term fluconazole for suppression[5]. However, because of the availability of safe, effective drugs for invasive candidiasis, emerging azole resistance, and high mortality, alternative drugs are now being increasingly used for *Candida* IE [7–14].

In the current investigation, we used a contemporary, prospective, international, multi-center cohort of patients with definite endocarditis to better evaluate the clinical characteristics, current antifungal treatment practices, and outcome of patients with *Candida* IE. Moreover, we compare and contrast *Candida* IE cases with non-fungal cases in order to highlight differences in epidemiology and outcomes.

Materials and Methods

Study Population

Patient data are derived from the International Collaboration of Endocarditis Prospective Cohort Study (ICE-PCS), a multi-national database of prospective cases of endocarditis. Details of the ICE-PCS have been described previously [15–17]. From June 2000 to August 2005, there were 2760 cases of definite IE contributed by sixty-one centers in 28 countries. Of the 2760 cases of definite IE, there were 33 cases due to Candida spp. All cases were classified as definite IE based on revised Duke criteria [18] and all cases were verified by the coordinating center (Duke University Medical Center). Fungal IE cases caused by organisms other than *Candida* (11 cases) were excluded from analysis. From each enrolled patient, data were collected from the index hospitalization and entered using an internet-based system. Data collected included demographics, symptoms associated with IE, underlying medical conditions, predisposing factors, clinical signs and symptoms, antifungal therapy, echocardiographic findings, associated complications and outcomes (stroke, embolic events, heart failure, intracardiac abscesses, persistently positive blood cultures, and death). Healthcare-associated IE was defined as either nosocomial infection or non-nosocomial healthcare-related infection. Nosocomial infection was defined as IE developing in a patient hospitalized for more than 48 hours before the onset of signs/symptoms consistent with IE. Death was determined at time of hospital discharge. Data on longer-term mortality was not collected.

Statistical Methods

Categorical variables were represented as frequencies and percentages of the specified group. The associations between clinical characteristics and *Candida* IE were measured using the Wilcoxon rank sum test for continuous variables and Chi square or Fisher's exact methods for categorical variables. For all tests, statistical significance was determined at the 0.05 level. All statistical analyses were performed using SAS software (version 9.1, SAS Institute, Cary, NC).

Results

Patient characteristics

Of the 2,749 patients with definite IE, 33 (1.2%) were *Candida* IE cases. The mean age of patients with *Candida* IE was 54.9 years. Patient characteristics including diabetes, renal disease, malignancy, intravenous drug use, and congenital heart disease were similar between the two groups (Table 1). Patients with *Candida* IE were less likely to be male (51.5% vs. 67.9%, p=0.04), more frequently had previous endocarditis (21.2% vs. 7.8%, p=0.005), and were more likely to have short term indwelling catheters (21.2% vs. 4.4%, p<0.0001). Among patients who had an invasive procedure within 60 days prior to onset of symptoms, CABG was more common among Candida IE patients (22.2% vs. 3.7%, p=0.007). Prosthetic valve IE was more common in *Candida* patients (48.8% vs. 19.6%, p=0.005), and *Candida* IE patients were more likely to have the infection classified as being healthcare-related (51.5% vs. 25.8%, p=0.009).

Clinical findings

Of patients with any IE etiology, most (75%; 2068/2749) experienced the first clinical manifestation less than one month before presentation, and timing of IE manifestations was similar between the two groups. The most common clinical manifestations among all patients were fever (79.5%; 2170/2728), new murmur (47.9%; 1053/2198), hematuria (22.1%; 607/2737), pulmonary edema (22.3%; 556/2491), and evidence of a vascular embolic event (15.9%; 435/2728). Overall, there was little difference of symptoms and signs at presentation between the *Candida* and non-fungal IE groups (Table 2). Thirteen-hundred sixteen (47.9%) of 2749 patients had surgery for endocarditis, and this was not different for the two groups.

Candida IE patients were more likely to have surgery indicated because of embolization (40% vs. 19.8%, p=0.054), persistent fungemia (33% vs. 9.9%, p=0.003), and myocardial abscess (46.7% vs. 22.2% p=0.026). By contrast, surgery for the indications of congestive heart failure (42.6% vs 13.3%, p=0.02) and valvular regurgitation (68% vs 40%, p=0.018) were more common in patients with non-fungal IE.

Complications

Congestive heart failure, systemic embolization after presentation, and stroke were common but similar in occurrence in the two groups. *Candida* IE was associated with persistently positive blood cultures (39.4% vs. 8.8%, p<0.001) (Table 3). Mortality at time of discharge was higher among *Candida* IE patients than non-fungal IE patients (30.3% vs 17%, p=0.046). This mortality difference was more pronounced among those patients who had surgery for this episode of IE (33.3% vs. 13.8%, p=0.03). Among 15 *Candida* IE patients who underwent surgical intervention for this episode of endocarditis, mortality at discharge was similar to *Candida* IE patients who did not have surgery (33.3% vs. 27.8%, p=0.26). Those patients who underwent surgical intervention were more likely to have previous IE (40% vs. 5.7%; p=0.016), previous surgery for IE (33.3% vs. 5.6%; p=0.009), paravalvular complications on ECHO (46.7% vs. 11.1%; p=0.015), and systemic embolization (46.7% vs. 16.7%; p=0.04) when compared with patients with *Candida* IE who were not treated with surgical intervention.

Organisms and Antifungal Treatment—Among the 33 patients with *Candida* IE, 16 (48%) were caused by *C. albicans*, 7 (21%) *C. parapsilosis*, 5 (15%) *C. glabrata*, and 3 (9%) *C. tropicalis*. Two (6%) isolates were not fully speciated. Treatment data were available for 27(82%) of 33 patients (Table 4). The most common antifungal agent used was amphotericin B (AmB), either conventional AMB (13/27; 48.1%) or a lipid formulation (3/27; 11.1%). Fluconazole was used in 12 (44.4%) of 27 patients. Primary therapy with fluconazole was used in 6 (54.5%) of 11 patients with complete fluconazole treatment data available. Ten patients (37%) received treatment with the newer antifungal agents caspofungin or voriconazole. Among patients who received single drug therapy, death occurred in 6(40%) of 15 patients; death occurred in 2(25%) of 8 who received sequential therapy. In only two cases combination therapy was used and both patients were alive at discharge. Two (20%) of 10 people who received newer therapies (caspofungin or voriconazole) died.

Discussion

Candida IE is an uncommon but frequently fatal infection [3,4,6]. A better understanding of the epidemiology, associated risk factors, and treatment methods is needed but difficult to obtain because of the rarity of cases and lack of large prospective cohorts. We compared contemporary clinically well-characterized cases of candidal IE to non-fungal IE cases registered as part of a large, multi-center, prospective dataset to better understand *Candida* IE. This analysis revealed several important observations regarding predisposing conditions, clinical findings, and treatment modalities.

Important risk factors or predisposing conditions for fungal endocarditis have been reported in recent, extensive reviews, and the most frequently reported are previous surgery, vascular lines, antibiotic use, underlying heart disease, prosthetic valves, and immunocompromising conditions [2–4,6]. We found similar predisposing conditions and noted several distinct differences among *Candida* and non-fungal IE cases. First, coronary artery bypass grafting (CABG) and prosthetic valve IE were significantly more common in *Candida* patients. An increase in previous CABG among *Candida* IE patients could be explained by CABG being performed in association with prosthetic valve surgery. Second, healthcare-associated IE was more common among patients with *Candida* IE. The increase in hospital-acquired *Candida* IE in general is consistent with recent data describing *Candida* as an emerging nosocomial bloodstream pathogen over the past decade[19].

The clinical findings and presentation of patients with *Candida* and non-fungal IE are very similar, as has been previously described [6]. The most important exceptions discovered in our review are related to indications for cardiac surgery. Of patients who had surgery during this episode of IE, those with *Candida* IE were more likely to have surgery based on the finding of myocardial abscess, or persistently positive blood cultures. Non-fungal cases more commonly had heart failure or valvular insufficiency as a reason for surgery.

There were few differences in complications and outcomes in the two groups except mortality. Candida IE mortality has been reported to be up to 80% in previous reviews[2-4,6], but variability in data collection and description of individual cases makes it difficult to determine an appropriate risk of death. Ellis and colleagues in a recent review demonstrated that the crude survival of patients with fungal endocarditis had increased over the past twenty years, from 14% before 1970 to 41% in the period of 1991–1995 [3]. Possible reasons for this improved survival were attributed to better echocardiographic techniques, earlier diagnosis of endocarditis, or better supportive care of ill patients [3]. Nearly one-third of patients in our series died during hospitalization, with mortality significantly greater than non-fungal cases. The mortality among patients with *Candida* IE in our series is surprisingly less than reported in previous reviews, but may be due to a multitude of factors. Diagnostic and treatment modalities have improved in the past decade, but likely cannot account for such a difference in survival. The inclusion of Candida cases only, which often have better survival compared to other fungal causes[3,4]; and the survival end-point defined at hospital discharge (compared to literature reviews where follow-up data were available for up to several years) may reflect the lower mortality in this series [3]. Finally, the use of newer antifungal therapies such as the echinocandins and lipid preparations of amphotericin B, not included in previous reviews because of lack of availability, may have an impact on outcomes and warrant further evaluation.

The traditional antifungal treatment of *Candida* IE is amphotericin B (6–8 weeks), often followed by fluconazole as suppression because of frequent relapse [5,6]. In addition, surgical intervention with valve replacement is generally recommended in most cases. The combination of antifungal and surgical therapy is purported to be more beneficial than antifungal therapy alone, although controlled studies have not been performed for confirmation [3,4,20]. In this cohort, surgical therapy was not associated with increased survival compared to antifungal therapy alone. It is encouraging that patients who did not receive surgical therapy fared relatively well; however, we speculate that the lack of a significant difference in the groups may reflect a combination of factors including increased morbidity and complications at presentation among patients who underwent surgery. Patients who underwent surgical intervention were more likely to have previous IE, previous surgery for IE, paravalvular complications on ECHO and systemic embolization. Although these may be important differences that influenced risk of death, with the limited number of patients evaluated it is difficult to draw conclusions with respect to the appropriate management.

In this cohort, an amphotericin B preparation was the most frequent drug used. Fluconazole was second most common, and was used either for primary or sequential therapy. Sequential therapy was frequently employed, and mortality in this group was lower than in patients who received a single agent. This probably results from selecting a subset of patients that lived long enough to "step down" to azole therapy. Length of therapy and dosages were not captured, so appropriate comparisons cannot be made. An important obstacle in successful antifungal therapy of Candida IE has been adverse events associated with prolonged amphotericin B administration. With the approval of new antifungal agents in the past several years, specifically echinocandins and newer azoles, questions have arisen about the role of these agents for the treatment of Candida IE. The echinocandins and voriconazole have shown efficacy and safety for the treatment of invasive candidiasis and candidemia [21,22]; however, data on use in endocarditis is limited to case reports [7–14]. Although some clinical success has been documented, selection bias may be present, and determinations of efficacy cannot be made. Our series reflects a shift in the treatment of Candida IE. Greater than one-third of patients received newer antifungal agents, particularly the echinocandin, caspofungin, and mortality among these patients (20%) was similar to other groups. Adverse events from drug use and isolate susceptibilities were not captured in the database, so the reasons for the use of these drugs are unclear.

Although an important aspect of this dataset is its overall size, and this represents the largest reported number of definite *Candida* IE cases compared to non-fungal cases, there are important limitations. The data were collected prospectively, but analysis was conducted retrospectively. The number of *Candida* cases is not large enough to draw conclusions regarding treatment, and long-term mortality data were not collected.

These data represent a multi-center collaborative effort describing a large cohort of definite endocarditis cases. There appear to be distinct epidemiologic features of *Candida* IE when compared to non-fungal cases. Indications for surgical intervention are different, mortality is increased, and alternative antifungal treatment options are increasingly used for this devastating disease. Large datasets or series, despite limitations, are needed to help better define *Candida* IE.

¹Only 27 patients had treatment data available

²Outcome at time of hospital discharge

 3 Treatment data other than drugs received were unavailable

⁴Patient received 1 month of VORI for suppressive therapy after an initial 11 weeks of treatment with CASPO and lipid AmB. Because of toxicity with VORI, CASPO was administered for an additional 8 weeks.

AmB= amphotericin B; Lipid AmB= liposomal AmB; CASPO=caspofungin; FLU=fluconazole; 5-FC=flucytosine; VORI=voriconazole
